

## **SOME STUDIES ON BREEDING SYSTEMS, PODSET AND YIELD IN CACAO (*Theobroma cacao* L.)**

**Kurar Sebastian Kalai**

### **ABSTRACT**

Experiments were carried out to understand the effect of breeding system, podset and carrying capacity on yield, in two diverse populations of cacao, viz., a naturalised population in Mount Saint Benedict and a plantation population in San Juan Estate, Gran Couva.

The population in Mount Saint Benedict was polymorphic for breeding system, consisting of self-incompatibles and self-compatibles at almost equal frequencies. The compatibility morphs were not significantly different in vegetative vigour or floral morphology. However, self-incompatibles produced significantly more flowers, set fewer pods and retained a greater percentage of pods to maturity compared to self-compatibles. However, the actual number of pods that reached maturity was the same for the two morphs, indicating that the carrying capacity of the trees was limiting yields.

In the plantation population in San Juan Estate, the THY clones showed a 1500 per cent increase in pod yield in hand pollinated treatments, compared to that under natural pollination. Although there were no significant differences in pod size between the two methods of pollination, the pod value showed an improvement under hand pollination. The per cent pods retained in the hand pollinated treatment was 71 compared to 84 under natural pollination. The results also showed that pods that were produced from later pollinations were more susceptible to cherelle wilting compared to those resulting from early pollinations. The study shows that under plantation conditions podset greatly limits yield and the implication of this to yield improvement is discussed both in the short-term

## ACKNOWLEDGEMENT

and in the long-term.

In an attempt to understand the scope for improving podset under natural pollination by improving the attractiveness of the flower, the natural podset of ICS clones was correlated to various floral characteristics. The results did not show any strong relationship. The size of flower parts, however, varied greatly among 239 clones from different populations investigated, but did not show a high correlation between them.

My appreciation is also extended to Professor J.P. Spencer for granting me a studentship at the Cocoa Research Unit, the University of the West Indies and to the European Economic Community for the financial support afforded through the European Development Fund (EDF) programme, which enabled me to undertake this study. Special thanks are due also to Mr. G. Mooteeram. Special thanks and appreciation are further extended to Mr. P.A. Lass of the Biscuit, Cake, Chocolate and Confectionery Alliance for his assistance.

Mr. Philippe Agoeilo's kindness and assistance in allowing the use of his facilities and access to the field site of San Juan Estate in Central Trinidad are gratefully acknowledged. The Monks of Mount Saint Benedict's Monastery are also hereby acknowledged for the access to the abandoned estate in Trinidad's Northern range.

The Director and the Board of Directors (1991-1995) of the PNG Cocoa and Coconut Research Institute are acknowledged for granting me study leave and assistance throughout this period. The humble assistance of Mr. Bale is treasured.

All the staff members of the Computer Centre of the University of the West Indies are thanked for their continuous support and kind assistance with the applications and programming with the UNIX and DOS operating systems. Special thanks to Susan, Jackie, Wayne, Zaid, Manya, Vaughn, Marlon and Eric.

I would like to render my sincere appreciation also to Dr. Michel Ducamp (CIRAD-CP) for his support throughout the period of this study and the comfort provided during my lowest moments especially throughout my period of adjustment. Without his assistance it would have been most disastrous. Thanks are also due to Messrs. W. Maharaj and R. Wisheed for their generous technical
